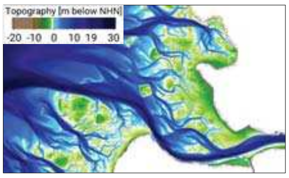
Feedbacks of sea-level rise induced topographic changes of the Wadden Sea on tidal dynamics

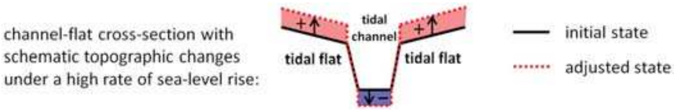
Benno Wachler, Caroline Rasquin, Norbert Winkel and Frank Kösters
Federal Waterways Engineering and Research Institute (BAW)

Introduction

The tidal flats of the Wadden Sea (German Bight) are of outstanding ecological value. In addition, tidal flats play a significant role for coastal defense and maintenance of navigational channels as they dissipate tidal and wave energy in the foreshore area.



In principle tidal flats of the Wadden Sea are capable to adapt to sea-level rise (SLR) by growth due to a more flood dominant tidal asymmetry with increased sediment import in tidal basins or internal redistribution of sediment between morphologic elements of tidal basins (transport from the channel to the flat, see sketch below).
However, estimates of tidal flat growth and associated critical SLR rates vary largely and have been proposed only for single tidal basins so far (e.g. van Goor et al. 2003, Dissanayake et al. 2012, Becherer et al. 2015). This study investigates feedbacks of hypothetic SLR-induced morphological changes of the entire Wadden Sea on tidal dynamics and whether these changes reinforce or compensate hydrodynamic effects, which arise from SLR alone.



Methods

In a German Bight model we set up a range of hypothetic topographic changes (TC) of the Wadden Sea (Fig. 1), which are considered likely under specific SLR scenarios such as 0.8 m within the 21st century (see right panel in Fig. 1). We combine these topographic scenarios with the respective SLR scenarios in 3D hydrodynamic simulations using the model UnTRIM (Casulli and Walters 2000), which allows the use of unstructured grids to optimally represent the complex topography of the German Bight with its tidal flats and channels.

The chosen topographic scenarios are based on:

- theoretical concepts about relations between estuarine geometric parameters and changes in tidal distortion with SLR (e.g. Friedrichs and Aubrey 1988),
- results of semi-empirical model studies (e.g. Van Goor et al. 2003) and
- results of process-based model studies (e.g. Dissanayake et al. 2012, Van Maanen et al. 2013, Becherer et al. 2015).

The considered topographic changes represent only a simplified scenario ignoring local or tidal basin specific differences of geometry, sediment availability, tidal range and biotic factors, such as abundance of micro and macro zoobenthos affecting the stability of sediment.

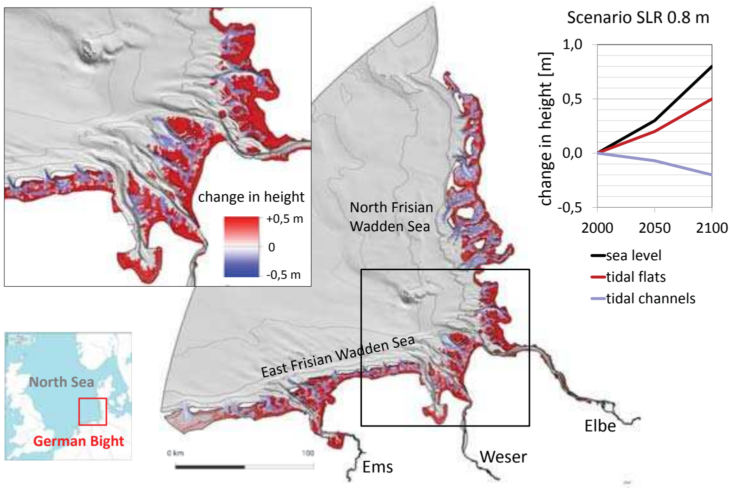


Figure 1: Applied schematic topographic changes considered likely under a SLR of 0.8 m within the 21st century.

Results

General observations:

- SLR effects as well as effects of the TC on maximum ebb current velocity (Fig. 2f,h) are not as prominent as on maximum flood current velocity (Fig. 2b,d).
- Effects of the considered TC on tidal currents are generally smaller (Fig. 2d,h) than effects of SLR (Fig. 2b,f), but can be in the same order of magnitude locally. Hence SLR-induced TC of the Wadden Sea should be considered for more realistic estimates of SLR effects on tidal dynamics.

Results (continued)

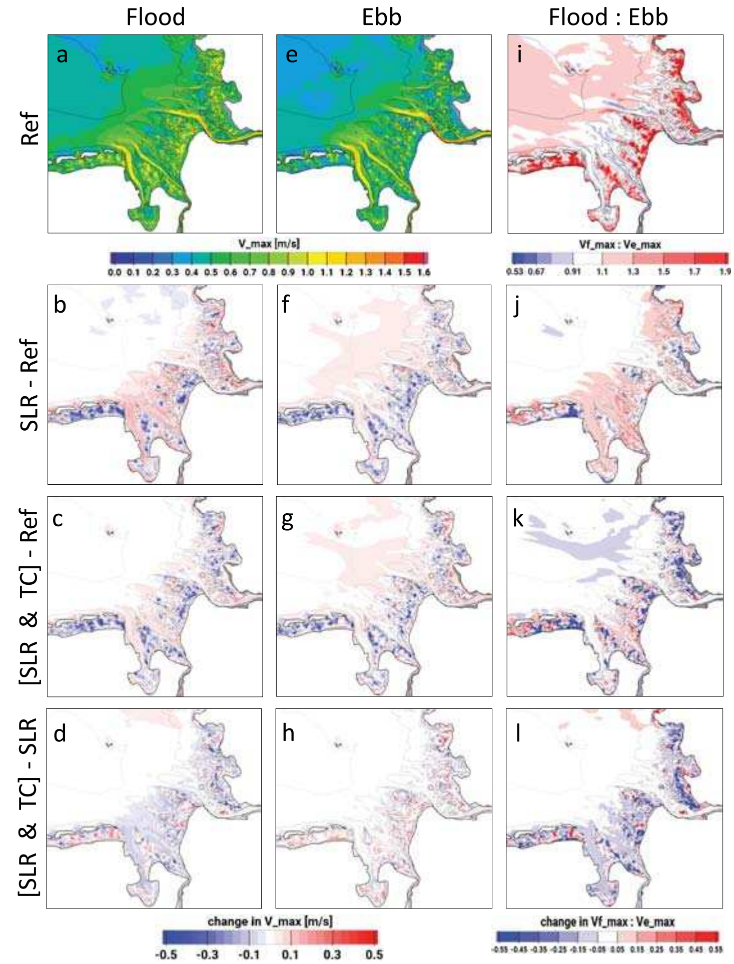

Figure 2: Maximum flood current velocity in the reference case (Ref) (a), changes due to sea-level rise (SLR - Ref) (b), changes due to sea-level rise and topographic changes ([SLR & TC] – Ref) (c) and residual changes due to topographic changes ([SLR & TC] – SLR) (d). The same for maximum ebb current velocity (e-h) and the ratio of maximum flood current velocity to maximum ebb current velocity (i-l). Depth contour lines are displayed for 0, 3, 10 and 30 m below NHN.

Feedbacks of the topographic changes on maximum <u>flood</u> current velocity:

- **Tidal channels:** While SLR induces an increase of maximum flood current velocity (Fig. 2b), the TC reduce the maximum flood current velocity (Fig. 2d).
- **Tidal flats:** Maximum flood current velocity is mainly decreased by the SLR except for very high tidal flats (Fig. 2b). This is partly compensated by the TC though not as uniform as compensational effects in the channels (Fig. 2d). SLR induced increases of maximum flood current velocity on very high tidal flats (Fig. 2b) are compensated by the TC (Fig. 2d).

Feedbacks of the topographic changes on maximum <u>ebb</u> current velocity:

- **Tidal channels:** Changes in maximum ebb current velocity due to SLR range from slightly decreasing to slightly increasing (Fig. 2f). Also the effects of the TC are locally different, either compensating or reinforcing SLR effects (Fig. 2h).
- **Tidal flats:** Maximum ebb current velocity is mainly decreased by SLR (Fig. 2f), which is mostly compensated by the TC (Fig. 2h). Similar to maximum flood current velocity, maximum ebb current velocity is increased by SLR on very high tidal flats (Fig. 2f), which is again mainly compensated by the TC (Fig. 2h).

Conclusions

Changes in tidal current velocities induced by sea-level rise are mostly compensated by the considered topographic changes of the Wadden Sea. The results demonstrate the significance of sea-level rise induced topographic changes in the Wadden Sea for estimating local effects of sea-level rise on tidal dynamics.
